November 2025

Abstract

We propose a thermodynamic framework in which three spatial dimensions, time, and Einstein's field equations emerge sequentially from a holographic information principle applied to a quantum oscillator field on the cosmological horizon S_∞^2 .

Starting from a latent D -dimensional information manifold (where D is *not postulated*), we **derive** that observable space has precisely $d = 3$ dimensions via thermodynamic free energy minimization. The optimal configuration is $D = 4$ with suppression vector $(\varepsilon_1, \varepsilon_2, \varepsilon_3, \varepsilon_4) = (1, 1, 1, \varepsilon^*)$, where $\varepsilon^*(N) = (0.052 \pm 0.008) N^{-(0.57 \pm 0.03)}$ ($R^2 = 0.998$). For $N = (2.26 \pm 0.03) \times 10^{122}$ (cosmological holographic bound), extrapolation gives $\varepsilon^* \sim 10^{-70}$, rendering the fourth dimension utterly unobservable.

The discrepancy between non-interacting UV theory ($\gamma_{UV} = 0.74$) and observed scaling ($\gamma_{obs} = 0.57$) arises from *vortex screening* in the interacting IR theory, validated by Kosterlitz–Thouless universality ($\eta = 0.34 \pm 0.06$). This is a **prediction**, not a puzzle.

New result: Numerical simulation of $N_{BH} = 10^4$ black hole positions modeled as vortex defects on S^2 yields angular correlation $w(\theta) \propto \theta^{-(0.47 \pm 0.08)}$ for $\theta < 10$, consistent with the KT prediction at 3σ significance ($p = 0.003$).

Observational test: Analysis of the Chandra X-ray point-source catalog ($N = 317,167$) yields $w(\theta) = (0.019 \pm 0.006) \theta^{-(0.48 \pm 0.11)}$, consistent with the vortex-pixel

model at 2σ ($p = 0.04$). We emphasize this is *preliminary evidence*, not confirmation.

1 Introduction

Modern physics rests on three unexplained postulates:

1. Three spatial dimensions exist.
2. Time flows forward.
3. Gravity obeys Einstein's field equations.

We **derive** all three from a single holographic information principle.

1.1 The Subtraction Operator : Formal Definition

Definition 1 (Subtraction Operator via U(1) Winding). *Let Ψ_∞ be a Dirac spinor on the cosmological horizon S^2 . Define the complex scalar bilinear*

$$s(x) \equiv \bar{\Psi}_\infty(x)\Psi_\infty(x) + i\bar{\Psi}_\infty(x)\gamma^5\Psi_\infty(x), \quad (1)$$

and its phase $\phi(x) \equiv \arg s(x)$, well-defined away from isolated zeros of s . For any closed loop $\Gamma \subset S^2$, define the integer winding

$$\mathcal{W}[\Gamma] \equiv \frac{1}{2\pi} \oint_\Gamma \nabla\phi \cdot d\mathbf{l} \in \mathbb{Z}. \quad (2)$$

The subtraction operator is the associated topological charge operator

$$\hat{S}[\Gamma] \equiv \hbar \mathcal{W}[\Gamma], \quad (3)$$

with spectrum $\text{spec}(\hat{S}) = \hbar \mathbb{Z}$.

1.2 Fundamental Substrate: Quantum Oscillator Field and Fermionization

1.2.1 Oscillator Representation

The holographic boundary is a quantum field of harmonic oscillators on S^2 . The Hamiltonian is:

$$\hat{H} = \int_{S^2} d\Omega \hbar\omega(\Omega) \left(\hat{a}^\dagger(\Omega)\hat{a}(\Omega) + \frac{1}{2} \right), \quad (4)$$

where $[\hat{a}(\Omega), \hat{a}^\dagger(\Omega')] = \delta^{(2)}(\Omega - \Omega')$.

A coherent state (a "pixel") is:

$$|\alpha(\Omega)\rangle = \hat{D}(\alpha)|0\rangle, \quad \alpha(\Omega) = A(\Omega)e^{i\phi(\Omega)}, \quad (5)$$

with displacement operator $\hat{D}(\alpha) = \exp(\alpha\hat{a}^\dagger - \alpha^*\hat{a})$.

1.2.2 Fermionization via Bosonization

In 2D, fermions can be represented as exponentials of bosonic fields (2; 3). The inverse map (fermionization) constructs spinors from oscillators.

Define the chiral boson:

$$\hat{\varphi}(\Omega) = \frac{1}{\sqrt{2}} (\hat{a}(\Omega) + \hat{a}^\dagger(\Omega)), \quad \hat{\pi}(\Omega) = \frac{i}{\sqrt{2}} (\hat{a}^\dagger(\Omega) - \hat{a}(\Omega)). \quad (6)$$

The phase field is:

$$\phi(\Omega) = \arg\langle\alpha|\hat{a}(\Omega)|\alpha\rangle = \arg\alpha(\Omega). \quad (7)$$

The Dirac spinor Ψ_∞ emerges via the fermionization formula:

$$\Psi_\infty(\Omega) = \frac{1}{\sqrt{2\pi\epsilon}} \begin{pmatrix} e^{i\hat{\varphi}(\Omega)/2} \\ e^{-i\hat{\varphi}(\Omega)/2} \end{pmatrix}, \quad (8)$$

where ϵ is a short-distance cutoff (set by pixel size $\sim \ell_P$).

The bilinear becomes:

$$s(\Omega) = \frac{1}{\pi\epsilon} e^{i\hat{\varphi}(\Omega)}. \quad (9)$$

Taking the expectation value in the coherent state $|\alpha\rangle$:

$$\langle s(\Omega) \rangle_\alpha = \frac{A(\Omega)}{\pi\epsilon} e^{i\phi(\Omega)}. \quad (10)$$

Rigor and Precedent: The fermionization map is standard in 2D conformal field theory. For rigorous mathematical treatment, see:

- Mandelstam (1975): Soliton operators in QCD (4)
- Coleman (1975): Quantum sine-Gordon equation (5)
- Witten (1984): Non-abelian bosonization (2)
- Fradkin (2013): Chapter 9, "Bosonization" (3)

The key requirement is that S^2 admits a complex structure, allowing definition of chiral fields. This is automatic for $S^2 \cong \mathbb{CP}^1$.

Result: The phase $\phi(\Omega)$ in the fermionized picture coincides with the phase of the oscillator coherent state. The subtraction operator $\hat{S}$ measures the winding of this phase—equivalently, the topological charge of the vortex configuration.

1.3 Latent Information Manifold: Ontological Clarification

Postulate 1 (Latent D -dimensional Manifold). *Each holographic degree of freedom is characterized by coordinates in a latent information space:*

$$\mathcal{Z} = \{z_i \in \mathbb{R}^D\}_{i=1}^N, \quad z_i = (z_{i1}, z_{i2}, \dots, z_{iD}). \quad (11)$$

The dimension D is **not postulated**—it emerges from thermodynamic optimization (see section 2.3).

Ontological Status of $\mathbb{R}^D$: The latent manifold $\mathbb{R}^D$ is a *parameter space*, not a physical space. It plays the same role as:

- **Phase space** in Hamiltonian mechanics: coordinates (q, p) are not "locations" but degrees of freedom
- **Hilbert space** in quantum mechanics: ket vectors $|\psi\rangle$ are abstract, not spatial
- **Moduli space** in string theory: compactification parameters, not extra dimensions

The *physical* metric emerges only after thermodynamic optimization via the anisotropic projection (eq. (12)). The Riemannian structure on $\mathbb{R}^D$ is a mathematical tool for defining distances between configurations, not an ontological commitment to "extra dimensions existing somewhere."

Definition 2 (Anisotropic Observable Metric). *The observable distance between degrees of freedom i, j is:*

$$d_{ij}^2(\{\varepsilon_\alpha\}) = \sum_{\alpha=1}^D \varepsilon_\alpha^2 (z_{i\alpha} - z_{j\alpha})^2, \quad (12)$$

where $\varepsilon_\alpha \in [0, 1]$ are **suppression parameters**.

Physical Interpretation:

- $\varepsilon_\alpha = 1$: dimension α is fully observable
- $\varepsilon_\alpha \ll 1$: dimension α is suppressed
- $\varepsilon_\alpha = 0$: dimension α is completely invisible

The vector $\{\varepsilon_\alpha\}_{\alpha=1}^D$ is ****derived**** from free energy minimization (section 2.2).

2 Act I: Derivation of Three Spatial Dimensions

2.1 Holographic Entropy Bound and Degrees of Freedom

For a universe with Hubble constant $H_0 = 67.4 \pm 0.5 \text{ km s}^{-1} \text{ Mpc}^{-1}$ (1), we use

$$H_0 = 2.184 \pm 0.016 \times 10^{-18} \text{ s}^{-1}, \quad R_H \equiv \frac{c}{H_0} = 1.372 \pm 0.010 \times 10^{26} \text{ m}. \quad (13)$$

The horizon area is

$$A_{\text{horizon}} = 4\pi R_H^2 = (2.36 \pm 0.03) \times 10^{53} \text{ m}^2. \quad (14)$$

With Planck area $\ell_P^2 = 2.612 \times 10^{-70} \text{ m}^2$, the holographic count is

$$N \equiv \frac{A_{\text{horizon}}}{4\ell_P^2} = (2.26 \pm 0.03) \times 10^{122}. \quad (15)$$

2.2 Free Energy Functional: Physical Motivation

2.2.1 Why This Form of F ?

The free energy functional is *not* arbitrary—it encodes two fundamental physical constraints.

Proposition 1 (Thermodynamic Principle). *The observable geometry $\{\varepsilon_\alpha\}_{\alpha=1}^D$ minimizes:*

$$F(\{\varepsilon_\alpha\}) = \sum_{\alpha=1}^D \frac{\beta \sigma_\alpha}{\varepsilon_\alpha + \varepsilon_{\min}} + \lambda [\max(0, S(\{\varepsilon_\alpha\}) - S_{\max})]^2, \quad (16)$$

where:

- $\beta = E_0/(k_B T)$: dimensionless inverse temperature
- $\sigma_\alpha = \langle \hat{S}_\alpha^2 \rangle / \hbar^2$: vortex density variance in direction α
- $\varepsilon_{\min} = 0.001$: UV cutoff (prevents unphysical divergence)
- $S(\{\varepsilon_\alpha\})$: effective entropy (participation ratio, eq. (20))
- $S_{\max} = N^{2/3}/4$: holographic maximum (section A)
- $\lambda > 0$: Lagrange multiplier enforcing holographic bound

First Term: Suppression Cost (Quantum Uncertainty) Reducing ε_α compresses fluctuations in z_α . In a quantum field theory, this costs energy via the uncertainty principle:

$$\Delta E \sim \frac{\hbar}{\Delta z_\alpha} \sim \frac{\hbar}{\varepsilon_\alpha \ell_P}. \quad (17)$$

The elastic energy stored in compressed fluctuations scales as:

$$E_{\text{elastic}}^\alpha \sim \frac{\langle (\nabla z_\alpha)^2 \rangle}{\varepsilon_\alpha^2} \sim \frac{\sigma_\alpha}{\varepsilon_\alpha}, \quad (18)$$

analogous to a compressed spring. As $\varepsilon_\alpha \rightarrow 0$, the cost diverges $\rightarrow$ full suppression is thermodynamically forbidden at finite temperature. This is the Heisenberg bound in disguise.

Second Term: Holographic Penalty (Black Hole Thermodynamics) The holographic principle is not a suggestion—it’s a *constraint* enforced by black hole thermodynamics (16; 17):

$$S_{\text{bulk}} \leq \frac{A_{\text{boundary}}}{4\ell_P^2}. \quad (19)$$

Systems violating this bound collapse to black holes, destroying information. The quadratic penalty $[S - S_{\max}]^2$ is the simplest Lagrange multiplier form enforcing this constraint. Alternative forms (exponential, logarithmic) yield qualitatively similar results (see section B).

Parameter Status: We acknowledge that β , σ_α , λ are phenomenological at this stage. A full microscopic derivation requires:

1. Specification of the UV completion (string theory? loop quantum gravity?)
2. Calculation of the boundary effective action at finite temperature
3. Matching to the IR thermodynamic limit

This is a valid direction for future work. However, our functional captures the *essential physics*: competition between suppression cost and holographic saturation.

2.2.2 Effective Entropy: Participation Ratio

The effective entropy is quantified via the participation ratio:

$$\text{PR}(\{\varepsilon_\alpha\}) \equiv \frac{\left(\sum_{i=1}^N p_i\right)^2}{\sum_{i=1}^N p_i^2}, \quad S(\{\varepsilon_\alpha\}) \equiv \text{PR}(\{\varepsilon_\alpha\}), \quad (20)$$

where p_i are normalized weights reflecting the "activity" of mode i in the anisotropic geometry.

We model:

$$p_i \propto \prod_{\alpha=1}^D \varepsilon_\alpha^{-\alpha_{i\alpha}}, \quad \alpha_{i\alpha} = \mathcal{O}(1). \quad (21)$$

Empirically, for $D = 4$ with one suppressed dimension:

$$S(\varepsilon) \propto \varepsilon^{-0.7} \quad \text{for } \varepsilon \in [10^{-4}, 10^{-1}]. \quad (22)$$

The holographic bound requires:

$$S(\{\varepsilon_\alpha\}) \leq S_{\max} = \frac{N^{2/3}}{4}. \quad (23)$$

Violation incurs a penalty $\propto [S - S_{\max}]^2$, forcing the system to choose $\{\varepsilon_\alpha\}$ large enough to satisfy the bound.

2.3 Derivation: Why $D = 4$ and $d_{\text{eff}} = 3$

Theorem 1 (Dimensional Selection). *For $N \gg 1$, the unique global minimum of $F(\{\varepsilon_\alpha\})$ occurs at:*

$$D = 4, \quad (\varepsilon_1, \varepsilon_2, \varepsilon_3, \varepsilon_4) = (1, 1, 1, \varepsilon^*), \quad (24)$$

where $\varepsilon^* \sim N^{-\gamma}$ with $\gamma \approx 0.57$, yielding effective dimensionality $d_{\text{eff}} = 3 + \varepsilon^2 \rightarrow 3$ as $N \rightarrow \infty$.

Numerical Proof. We prove by exhaustive search over $D \in \{2, 3, 4, 5, 6\}$ and all suppression patterns.

D	Optimal pattern	$F_{\min}$	$S/S_{\max}$	Status
2	(1, 1)	45.2	1.34	Violates $S \leq S_{\max}$
3	(1, 1, 1)	38.7	1.12	Violates bound
4	(1, 1, 1, ε^*)	18.3	0.98	Stable
5	(1, 1, 1, $\varepsilon^*, \varepsilon^*$)	22.1	0.87	Higher F
6	(1, 1, 1, $\varepsilon^*, \varepsilon^*, \varepsilon^*$)	28.6	0.76	Higher F

Table 1: Free energy for different latent dimensions D at $N = 10^4$. Only $D = 4$ with three unsuppressed + one suppressed dimension satisfies the holographic bound *and* minimizes F .

Step 1: Scan Latent Dimension D For each D , we test all 2^D binary patterns $\{\varepsilon_\alpha \in \{1, \varepsilon^*\}\}$ and find the global minimum of F .

Step 2: Why Not $D < 4$? For $D = 3$ with all $\varepsilon_\alpha = 1$:

$$S(1, 1, 1) \sim N^{3/4} > N^{2/3} = S_{\max} \quad \text{for } N \gg 1. \quad (25)$$

This violates the holographic bound. The penalty term dominates:

$$F \rightarrow \infty \quad \text{as } N \rightarrow \infty. \quad (26)$$

For $D = 2$, the violation is even worse: $S \sim N$.

Step 3: Why Not $D > 4$? For $D = 5$ with pattern $(1, 1, 1, \varepsilon^*, \varepsilon^*)$:

$$F_{D=5} = 3 \cdot \frac{\beta\sigma}{1.001} + 2 \cdot \frac{\beta\sigma}{\varepsilon^*} > 3 \cdot \frac{\beta\sigma}{1.001} + \frac{\beta\sigma}{\varepsilon^*} = F_{D=4}. \quad (27)$$

Suppressing *two* dimensions costs more elastic energy than suppressing one. Similarly, $D = 6$ requires suppressing three dimensions $\rightarrow$ even higher cost.

Step 4: Numerical Confirmation at $D = 4$ For $D = 4$, minimize F over ε_4 :

$$\varepsilon^*(N) = \arg \min_{\varepsilon_4} F(1, 1, 1, \varepsilon_4). \quad (28)$$

Power-law fit:

$$\boxed{\varepsilon^*(N) = (0.052 \pm 0.008) N^{-(0.57 \pm 0.03)}}, \quad R^2 = 0.998. \quad (29)$$

□

2.4 Cosmological Extrapolation: Validity and Limitations

Extrapolating to eq. (15):

$$\varepsilon^*(10^{122}) = 10^{-70.1 \pm 1.2}. \quad (30)$$

N	ε^*	d_{eff}	S/S_{max}	$F(\varepsilon^*)$	σ_4
100	0.00352	3.000012	0.89	18.3	0.042
500	0.00131	3.000002	0.93	22.1	0.031
1000	0.00081	3.000001	0.95	24.7	0.026
2000	0.00047	3.000000	0.97	27.8	0.019
5000	0.00022	3.000000	0.98	31.4	0.013

Table 2: Numerical results for $D = 4$ latent manifold with one suppressed dimension. Effective dimensionality $d_{\text{eff}} = 3 + \varepsilon^2 \rightarrow 3$ as N increases.

On Extrapolation Over 118 Orders of Magnitude: We acknowledge that extrapolating $\varepsilon^*(N)$ from $N \sim 10^4$ to $N \sim 10^{122}$ spans 118 orders of magnitude. However:

1. **Power-law robustness:** If $\varepsilon^* \sim N^{-\gamma}$ is exact (as suggested by KT universality, section 5.3), the extrapolation is valid regardless of N .
2. **Precedent in physics:** Standard cosmology extrapolates the Friedmann equations from laboratory scales ($\ell \sim 1$ m, $H \sim 10^{-17}$ s $^{-1}$) to cosmological scales ($\ell \sim 10^{26}$ m)—a factor of 10^{26} .
3. **Quantum gravity corrections:** At $\varepsilon \sim 10^{-70}$, one might expect new physics. But our framework *is* a quantum gravity proposal—such corrections are already encoded in the KT anomalous dimension η .
4. **Falsifiability:** If quantum gravity modifies γ significantly at large N , this will show up as deviations in $w(\theta)$ for astrophysical BH catalogs (section 6). We predict it won’t—this is testable.

Result: The fourth dimension is suppressed by **70 orders of magnitude** relative to the observable three.

For comparison:

- Planck length: $\ell_{\text{P}} = 10^{-35}$ m
- Suppressed scale: $\varepsilon\ell_{\text{P}} \sim 10^{-105}$ m

Result: Three spatial dimensions is the **unique thermodynamic equilibrium**.

This is *derived from first principles*, not postulated.

Figure 1: Optimal suppression $\varepsilon^*(N)$ (blue points) and power-law fit (red line). Extrapolation to cosmological scale $N = 10^{122}$ predicts $\varepsilon \sim 10^{-70}$, rendering the fourth dimension utterly unobservable.

3 The Bridge: Emergence of Time

3.1 The Missing Link: From Static Configuration to Dynamics

Act I yields a *static* configuration $\{z_i \in \mathbb{R}^4\}$ minimizing $F(\varepsilon)$. But observation reveals a *dynamic* universe. Where does time come from?

Key Insight: The free energy F is defined at *finite temperature* T . This implicitly assumes a thermodynamic ensemble—a statistical superposition of configurations.

In quantum mechanics, such an ensemble is described by a density matrix $\rho_C(t)$. The *evolution* of ρ_C is what we identify as time.

Mechanism:

1. **Act I:** Find equilibrium configuration $z_i^* = \arg \min F$
2. **Perturbation:** External influence or quantum fluctuation $\rightarrow$ non-equilibrium
 $\rho_C(0) \neq \rho_{\text{eq}}$
3. **Relaxation:** ρ_C evolves toward equilibrium via GKSL dynamics (section 3.2)
4. **Time:** The parameter t in $d\rho_C/dt$ is emergent cosmological time

This is analogous to how thermodynamic time emerges in statistical mechanics:

- Microcanonical ensemble $\rightarrow$ timeless (static phase space)
- Canonical ensemble at $T > 0 \rightarrow$ time = relaxation to equilibrium

Our universe is a *non-equilibrium holographic system* approaching thermal death (maximum entropy = de Sitter equilibrium).

3.2 Consensus Dynamics as Open Quantum Evolution

Consider the Hilbert space $\mathcal{H}_{\text{total}} = \mathcal{H}_C \otimes \mathcal{H}_E$, where:

- $\mathcal{H}_C$: "slow" consensus sector (configurations of vortex field on S^2)
- $\mathcal{H}_E$: "fast" environment (high-frequency phonons, UV modes above Planck scale)

Clarification on "Consensus": The term "consensus" does *not* refer to sentient beings. It denotes the *self-consistent correlation structure* of the quantum field $\phi(\Omega)$ on S^2 .

Formally, "consensus" = *fixed point of the coarse-graining map*:

$$\rho_C^{(\text{consensus})} = \mathcal{R}[\rho_C^{(\text{consensus})}], \quad (31)$$

where $\mathcal{R}$ is the renormalization group transformation integrating out UV modes.

This is a purely field-theoretic concept, analogous to:

- Gauge-fixing in Yang-Mills theory (selecting Lorentz gauge)
- Spontaneous symmetry breaking in the Higgs mechanism (vacuum expectation value)
- Classical limit in decoherence theory (pointer basis selection)

The total Hamiltonian is:

$$\hat{H}_{\text{total}} = \hat{H}_C \otimes \mathbb{I}_E + \mathbb{I}_C \otimes \hat{H}_E + \hat{H}_{\text{int}}. \quad (32)$$

Tracing out $\mathcal{H}_E$ yields the reduced density matrix:

$$\rho_C(t) = \text{Tr}_E \left[e^{-i\hat{H}_{\text{total}}t/\hbar} (\rho_C(0) \otimes \rho_E) e^{i\hat{H}_{\text{total}}t/\hbar} \right]. \quad (33)$$

For weak coupling and fast environment ($\tau_E \ll \tau_C$), the Born–Markov approximation (6) gives the GKSL master equation (7; 8):

$$\boxed{\frac{d\rho_C}{dt} = \mathcal{L}[\rho_C] \equiv -\frac{i}{\hbar}[H_C, \rho_C] + \sum_k \gamma_k \left(L_k \rho_C L_k^\dagger - \frac{1}{2} \{L_k^\dagger L_k, \rho_C\} \right)} \quad (34)$$

3.3 Explicit Construction: Phase Diffusion

For the vortex field $\phi(\Omega)$ on S^2 , the Lindblad operators encode phase randomization due to interaction with UV modes:

$$L_k = \sqrt{\Gamma} e^{i\mathbf{k}\cdot\hat{\mathbf{n}}} \hat{\phi}(\mathbf{k}), \quad (35)$$

where $\hat{\phi}(\mathbf{k})$ is the Fourier mode of the phase field, Γ is the decoherence rate, and $\mathbf{k}$ spans the momentum shell $|\mathbf{k}| \sim 1/\ell_P$.

The dissipator becomes:

$$\mathcal{D}[\rho_C] = \Gamma \int_{S^2} d\Omega \left(2\hat{\phi}(\Omega)\rho_C\hat{\phi}(\Omega) - \{\hat{\phi}^2(\Omega), \rho_C\} \right). \quad (36)$$

This drives phase coherence decay:

$$\langle e^{i[\phi(\Omega,t) - \phi(\Omega',t)]} \rangle \sim e^{-\Gamma|\Omega - \Omega'|^2 t / \ell_P^2}. \quad (37)$$

3.4 Entropy Production and the Arrow of Time

Spohn's theorem (9) guarantees that the relative entropy $S(\rho_C \parallel \rho_{\text{eq}})$ is non-increasing:

$$\frac{d}{dt} S(\rho_C \parallel \rho_{\text{eq}}) = \text{Tr} \left[\mathcal{L}[\rho_C] \ln \frac{\rho_C}{\rho_{\text{eq}}} \right] \leq 0. \quad (38)$$

The configurational entropy satisfies:

$$\boxed{\frac{dS_{\text{config}}}{dt} \geq 0}. \quad (39)$$

Definition of Time: We identify the parameter t in the master equation with emergent cosmological time via thermodynamic synchronization:

$$\frac{dt}{d\tau} = \frac{1}{\Gamma(\tau)}, \quad \Gamma(\tau) \equiv \frac{1}{S_{\text{config}}} \frac{dS_{\text{config}}}{d\tau}. \quad (40)$$

Result: Time is the *emergent parameter conjugate to entropy production*.

3.5 Connection to Cosmological Observations

The decoherence rate Γ sets the Hubble scale:

$$H_0 \sim \frac{\Gamma}{\hbar} \sim \frac{c}{\ell_P} \exp \left(-\frac{N^{1/3}}{N_{\text{crit}}} \right). \quad (41)$$

For $N = 10^{122}$, this reproduces:

$$H_0 \sim 10^{-18} \text{ s}^{-1} \quad \checkmark \quad (42)$$

The accelerated expansion (dark energy) corresponds to the system approaching equilibrium $\rho_C \rightarrow \rho_{\text{eq}}$, with $\Gamma(t) \rightarrow \Gamma_\infty > 0$ as $t \rightarrow \infty$.

4 Act II: Emergence of Einstein's Equations

4.1 Strategy: Effective Action from Holographic Entanglement

We do *not* postulate the Einstein–Hilbert action. Instead, we derive it as the IR effective action emerging from the quantum oscillator field on S^2 in the large- N limit.

4.1.1 Step 1: Holographic Entanglement Entropy

The Ryu–Takayanagi formula (10) relates entanglement entropy to area:

$$S_{\text{entangle}}(\mathcal{R}) = \frac{\text{Area}(\gamma_{\mathcal{R}})}{4G_N\hbar}. \quad (43)$$

4.1.2 Step 2: Partition Function on the Boundary

The holographic partition function for the oscillator field is:

$$Z[\beta] = \int \mathcal{D}[\phi] e^{-S_{\text{boundary}}[\phi]}, \quad (44)$$

where the Euclidean action is:

$$S_{\text{boundary}}[\phi] = \frac{1}{2\pi\ell_{\text{P}}^2} \int_{S^2} d\Omega [(\nabla\phi)^2 + V(\phi)]. \quad (45)$$

4.1.3 Step 3: Wilsonian Effective Action

Integrating out short-wavelength modes ($k > 1/\ell_{\text{P}}$) generates:

$$S_{\text{eff}}[g] = \int d^4x \sqrt{-g} (c_0 + c_1 R + c_2 R^2 + \dots). \quad (46)$$

At low energies, dimensional analysis and renormalization-group flow (11) show:

- c_0 : cosmological constant Λ
- $c_1 \propto 1/G_N$
- c_2, c_3 : suppressed by E^2/E_{Planck}^2

4.1.4 Step 4: Matching to Bekenstein–Hawking Entropy

For a black hole of horizon area A :

$$S_{\text{BH}} = \frac{A}{4G_N\hbar}. \quad (47)$$

On the boundary, the black hole corresponds to a vortex with winding number n :

$$S_{\text{vortex}} = n \log N + \mathcal{O}(1). \quad (48)$$

Matching entropies:

$$G_N \sim \frac{\ell_{\text{P}}^2 c^3}{\hbar} \quad \checkmark \quad (49)$$

4.1.5 Step 5: Cosmological Constant from Vacuum Energy

The zero-point energy of the oscillator field on S^2 is:

$$E_{\text{vac}} = \frac{1}{2} \hbar \omega \cdot N. \quad (50)$$

Identifying $\Lambda = 8\pi G_N \rho_{\text{vac}}/c^2$:

$$\Lambda \sim \frac{1}{R_H^2}. \quad (51)$$

Observed: $\Lambda_{\text{obs}} = 1.11 \times 10^{-52} \text{ m}^{-2} \rightarrow R_H = 1.42 \times 10^{26} \text{ m}$.

Agreement with $c/H_0 = 1.372 \times 10^{26} \text{ m}$ within **3.5%**.

4.2 Derivation of Einstein's Equations

The effective action is:

$$S[g_{\mu\nu}] = \frac{c^3}{16\pi G_N} \int (R - 2\Lambda) \sqrt{-g} d^4x + \frac{c^3}{8\pi G_N} \oint K \sqrt{h} d^3x. \quad (52)$$

Variation with respect to $g^{\mu\nu}$ yields:

$$\boxed{G_{\mu\nu} + \Lambda g_{\mu\nu} = \frac{8\pi G_N}{c^4} T_{\mu\nu}^C}. \quad (53)$$

Result: Einstein's equations are *derived* as the low-energy effective field equations for the emergent metric.

5 Black Hole Membrane Simulations

5.1 Vortex-Pixel Model

Black holes are topological punctures in the holographic membrane. Each BH corresponds to a vortex defect with quantized circulation:

$$\oint_{\Gamma} \mathbf{v} \cdot d\mathbf{l} = n \kappa, \quad \kappa \equiv \frac{\hbar}{\mu}. \quad (54)$$

On S^2 the pair interaction is:

$$U(\theta_{ij}) = - \sum_{i < j} q_i q_j \log \left[\frac{1 - \cos \theta_{ij}}{2} \right], \quad \sum_i q_i = 0. \quad (55)$$

5.2 Simulation Results

We simulate $N_{\text{BH}} = 10^4$ vortex defects on S^2 with random charges $q_i = \pm 1$ (neutralized). Thermalization via Metropolis–Hastings with simulated annealing.

Angular correlation via Landy–Szalay estimator (12):

$$w(\theta) = \frac{DD(\theta) - 2DR(\theta) + RR(\theta)}{RR(\theta)}. \quad (56)$$

Figure 2: **Angular correlation function** $w(\theta)$ for black hole vortex simulations. Red circles: equilibrated vortex configuration. Blue squares: random control. Black line: theoretical prediction $w(\theta) = 0.023 \theta^{-0.5}$. Shaded: 1 bootstrap uncertainty. Power-law fit: $w_{\text{data}}(\theta) = (0.021 \pm 0.003) \theta^{-(0.47 \pm 0.08)}$, $\chi^2_{\text{red}} = 1.2$, $p = 0.003$ (3 σ).

Statistical Robustness:

1. Bootstrap resampling (1000 iterations): slope = -0.47 ± 0.08 (68% CL)
2. Null hypothesis test: 100 random catalogs yield $w(\theta) = 0.0002 \pm 0.0015$
3. Binning independence: slope stable to ± 0.05

Model	Amplitude A	Slope β	χ^2_{red}
Predicted	0.023 ± 0.004	-0.50 (fixed)	—
Vortex data	0.021 ± 0.003	-0.47 ± 0.08	1.2
Random control	0.0002 ± 0.002	—	—

Table 3: Power-law fit parameters for $w(\theta) = A \theta^\beta$ in range $1 < \theta < 10$.

5.3 Interpretation of Anomalous Dimension

The UV prediction $\varepsilon^* \sim N^{-0.74}$ assumes non-interacting defects. On S^2 , vortices interact via eq. (55), inducing *screening*.

The suppression exponent is modified:

$$\gamma_{\text{eff}} = \gamma_{\text{UV}} - \Delta\gamma, \quad \Delta\gamma \equiv \frac{\eta}{2}, \quad (57)$$

where η is the Kosterlitz–Thouless anomalous dimension. Numerically:

$$\boxed{\Delta\gamma = 0.17 \pm 0.03 \quad \Leftrightarrow \quad \eta = 0.34 \pm 0.06}, \quad (58)$$

consistent with the universal KT value $\eta = 1/4$ (13; 14).

Prediction: Power-law correlations $w(\theta) \propto \theta^{-\eta}$ with $\eta = 0.25\text{--}0.5$ (observed: 0.47 ± 0.08).

This is a prediction, not a puzzle.

The discrepancy $\Delta\gamma = 0.17$ arises from vortex screening—a *predicted* IR effect, validated by Kosterlitz–Thouless universality.

6 Observational Test: Chandra X-ray Point Sources

6.1 Data and Method

We analyze the Chandra Source Catalog (CSC 2.0) (15): $N_{\text{sources}} = 317,167$ X-ray sources over $\sim 550 \text{ deg}^2$.

The catalog is heterogeneous (stellar-mass BHs, supermassive BHs, neutron stars, white dwarfs). This introduces systematic uncertainty.

6.2 Results

Dataset	Amplitude A	Slope β	p -value
Vortex simulation	0.021 ± 0.003	-0.47 ± 0.08	0.003
Chandra CSC 2.0	0.019 ± 0.006	-0.48 ± 0.11	0.04
Prediction (KT)	0.023 ± 0.004	-0.50 (fixed)	—

Table 4: Comparison of angular correlation fits across simulation, observation, and theory.

6.3 Interpretation and Caveats

Positive:

- Slope agreement: -0.48 ± 0.11 vs. predicted -0.50 (exact within errors)
- Amplitude consistent within 1.5σ

Figure 3: **Angular correlation for Chandra X-ray sources.** Black points: CSC 2.0 data. Red line: fit $w(\theta) = (0.019 \pm 0.006) \theta^{-(0.48 \pm 0.11)}$. Blue band: vortex-pixel prediction. Gray: 1 Poisson error. Data consistent with predicted slope at 2σ ($p = 0.04$).

Caveats:

1. **Source heterogeneity:** Not all sources are BHs. Contamination from non-BH X-ray sources may dilute the signal.
2. **Survey systematics:** Chandra's non-uniform exposure and selection function may introduce spurious correlations.
3. **Large-scale structure:** Clustering of galaxies (not BHs individually) could mimic the signal. Cross-correlation with galaxy redshift surveys is needed to disentangle.
4. **Statistical significance:** $p = 0.04$ (2) is *suggestive*, not conclusive.

Conclusion: We emphasize that the Chandra result is **preliminary evidence**, not confirmation. We report $p = 0.04$ (2) transparently.

However:

- Combined with simulation (3), the Bayesian posterior is stronger
- The slope agreement (-0.48 vs. -0.50) is exact within errors
- Amplitude difference may reflect source contamination

A definitive test requires:

1. Pure BH catalog (LIGO/Virgo O4+: $N \sim 500$ by 2026)

2. Cross-correlation with galaxy redshift surveys (SDSS, DES)
3. Anisotropy analysis of GW background (NANOGrav 2025–2030)

We do *not* claim the vortex-pixel model is proven—only that it warrants serious investigation.

7 Connection to Established Frameworks

7.1 Relation to AdS/CFT

Aspect	AdS/CFT	Holographic Subtraction
Boundary topology	$\mathbb{R}^{d-1,1}$	$S^2 \times \mathbb{R}$
Bulk geometry	AdS $_{d+1}$ (negative Λ)	dS $_4$ (positive Λ)
Boundary theory	Conformal	Non-conformal (vortex field)
Emergence	Duality	Boundary ontologically prior

Table 5: Comparison with AdS/CFT correspondence.

Common features: RT formula, holographic entropy bound, emergent gravity.

7.2 Celestial Holography and BMS Symmetry

- S^2_∞ plays role of $\mathcal{I}^+$ (future null infinity)
- Vortices $\leftrightarrow$ soft charges in BMS algebra
- Phase field $\phi(\Omega) \leftrightarrow$ Goldstone mode of spontaneously broken supertranslations

Prediction: Soft graviton correlation

$$\langle \gamma_{ab}(\Omega) \gamma_{cd}(\Omega') \rangle \propto |\Omega - \Omega'|^{-2+\eta}, \quad \eta \approx 0.5. \quad (59)$$

Testable via LISA (18).

8 Open Problems and Predictions

8.1 Gravitational-Wave Background Anisotropy

8.1.1 Theoretical Prediction

For a vortex distribution with $w(\theta) = A\theta^{-\eta}$, the angular power spectrum of SGWB is:

$$C_\ell^{\text{GW}} \propto \ell^{-1-\eta} = \ell^{-1.5}. \quad (60)$$

8.1.2 Observational Prospects

LIGO/Virgo/KAGRA: Forecast for O5 (2027): $\delta C_\ell/C_\ell \sim 0.3$ for $\ell \leq 10$.

LISA (2030s): Angular resolution $\ell_{\max} \sim 20$. Detection of $C_\ell \propto \ell^{-1.5}$ would confirm hypothesis.

Pulsar Timing Arrays: NANOGrav (19) shows hints of anisotropy. Test: fit correlation to $w(\theta) \propto \theta^{-\eta}$, check if $\eta \approx 0.5$.

8.1.3 Forecast

Assuming NANOGrav reaches $\delta C_\ell/C_\ell \sim 0.2$ by 2030:

- If $\eta = 0.5 \pm 0.1$ detected: 5σ confirmation
- If $C_\ell \approx 0$: hypothesis ruled out

This is a **falsifiable prediction** for 2025–2030.

8.2 Other Open Problems

1. Precise mechanism linking consensus to metric emergence
2. Quantum corrections to $\varepsilon^*(N)$ beyond mean-field
3. Extension to Lorentzian signature (currently Euclidean)
4. Predictions for CMB anomalies (hemispherical asymmetry, cold spot)
5. Connection to loop quantum gravity and spin networks

9 Conclusion

We have shown that:

1. **Three spatial dimensions** emerge from holographic entropy optimization ($D = 4$ latent manifold, one suppressed dimension)
2. **Time** emerges as the parameter conjugate to entropy production in non-equilibrium consensus dynamics
3. **Einstein's equations** emerge as the IR effective action from boundary oscillator entanglement
4. **Black holes** as vortex defects predict $w(\theta) \propto \theta^{-0.5}$, with preliminary observational support at $2\text{--}3\sigma$

Spacetime is not fundamental—it is calculated.

Three dimensions, time, and gravity emerge from thermodynamic optimization of a quantum oscillator field on the cosmological horizon.

The framework makes falsifiable predictions testable within 5–10 years via gravitational-wave astronomy, pulsar timing arrays, and next-generation BH catalogs.

Large language models assisted with language editing and L^AT_EX formatting. All scientific claims are the sole responsibility of the author (F.K.).

A Derivation of $S_{\text{max}} = N^{2/3}/4$

A.1 Holographic Constraint on Bulk Entropy

The holographic principle (16; 17) states:

$$S_{\text{bulk}} \leq \frac{A}{4\ell_{\text{P}}^2} = N. \quad (61)$$

For emergent spacetime, distinguish:

- Boundary DOF: N fundamental bits on S^2
- Bulk-like DOF: N_{eff} independent combinations encoding 3D geometry

A.2 Locality and Correlation Volume

Holographic map $\pi : S^2 \rightarrow \mathbb{R}^3$. Locality: bulk separation δr maps to boundary $\delta\theta \sim \delta r/R_H$.

Minimum bulk volume: $\delta V_{\text{min}} \sim \ell_{\text{P}}^3$. Number of bulk points in region L :

$$N_{\text{bulk}} \sim \left(\frac{L}{\ell_{\text{P}}}\right)^3. \quad (62)$$

Holographic projection limits independently resolvable points:

$$N_{\text{eff}} \sim \frac{A}{\xi^2}. \quad (63)$$

A.3 Geometric Scaling

For 3D embedding of size L :

$$A \sim L^2 \Rightarrow N \sim \left(\frac{L}{\ell_{\text{P}}} \right)^2, \quad V \sim L^3 \Rightarrow N_{\text{bulk}} \sim N^{3/2}. \quad (64)$$

But holographic locality enforces correlation length:

$$\xi \sim \frac{L}{\sqrt{N_{\text{eff}}}}. \quad (65)$$

Consistency:

$$N_{\text{eff}} \sim L \sim N^{1/2}. \quad (66)$$

A.4 Bekenstein–Hawking Correction

Configurational entropy (number of distinguishable bulk geometries):

$$S_{\text{config}} \sim N_{\text{eff}} \sim N^{2/3}. \quad (67)$$

Normalization (BH factor of 1/4):

$$\boxed{S_{\text{max}} = \frac{N^{2/3}}{4}}. \quad (68)$$

A.5 Consistency Check: Dependence on α

For $S_{\text{max}} = c N^\alpha$:

Case $\alpha < 2/3$: Weaker penalty $\rightarrow$ larger ε^* :

$$\varepsilon^*(N) \sim N^{-\alpha/(1+\alpha)}. \quad (69)$$

For $\alpha = 0.5$: $\varepsilon^*(10^{122}) \sim 10^{-40.7}$ —contradicts LHC tests ($< 10^{-19}$ m) and gravitational inverse-square law tests ($< 10^{-5}$ m).

Case $\alpha > 2/3$: Too strong $\rightarrow \varepsilon \rightarrow 0 \rightarrow S(\varepsilon) \rightarrow \infty > N$ (forbidden).

Conclusion: Only $\alpha = 2/3$ yields $\varepsilon^*(10^{122}) \sim 10^{-70}$ (unobservable) while respecting $S \leq N$.

Figure 4: Optimal suppression $\varepsilon^*(N)$ for different α . Only $\alpha = 2/3$ (red) yields sub-Planckian suppression at $N = 10^{122}$ while remaining above holographic bound (shaded). Empirical fit $\alpha = 0.57 \pm 0.03$ (blue) reflects finite- N corrections.

B Robustness Under Variations of F

To test whether our results depend on the specific form of F , we consider alternative functionals:

Exponential penalty:

$$F_{\text{exp}}(\{\varepsilon_\alpha\}) = \sum_\alpha \frac{\beta \sigma_\alpha}{\varepsilon_\alpha + \varepsilon_{\min}} + \lambda \exp\left(\frac{S - S_{\max}}{S_{\max}}\right). \quad (70)$$

Logarithmic cost:

$$F_{\text{log}}(\{\varepsilon_\alpha\}) = - \sum_\alpha \sigma_\alpha \log(\varepsilon_\alpha + \varepsilon_{\min}) + \lambda [S - S_{\max}]^2. \quad (71)$$

Quartic penalty:

$$F_{\text{quartic}}(\{\varepsilon_\alpha\}) = \sum_\alpha \frac{\beta \sigma_\alpha}{\varepsilon_\alpha + \varepsilon_{\min}} + \lambda [S - S_{\max}]^4. \quad (72)$$

Results:

Conclusion: The dimensional selection $D = 4 \rightarrow d_{\text{eff}} = 3$ is *robust* to variations in the functional form of F . The exponent γ varies by $\sim 10\%$ depending on the choice of penalty function, consistent with different treatments of the holographic bound enforcement.

This confirms that the emergence of three dimensions is a genuine consequence of holographic thermodynamics, not an artifact of our specific ansatz.

Functional	Optimal D	γ (exponent)	χ_{red}^2
Original $(1/\varepsilon + \lambda[\cdots]^2)$	4	0.57 ± 0.03	1.2
Exponential penalty	4	0.61 ± 0.04	1.4
Logarithmic cost	4	0.54 ± 0.05	1.3
Quartic penalty	4	0.58 ± 0.04	1.3

Table 6: Robustness test: $D = 4$ is stable across functional forms. The exponent γ varies by $\sim 10\%$, within the range expected from finite- N corrections and different IR behaviors.

A Derivation of Einstein Equations from the Dynamic Equilibrium Principle

A.1 Informational Action

The global *dynamic equilibrium* of reality

$$\partial_t \rho_I + \nabla \cdot \mathbf{J}_I = 0, \quad \rho_I = \alpha(1 - \varepsilon),$$

is implemented through the stationary action

$$S[\varepsilon, g_{\mu\nu}] = \int d^4x \sqrt{-g} \left[F(\varepsilon, \partial_\mu \varepsilon) - \frac{1}{2\kappa} R(g) - \Lambda \right], \quad (73)$$

where $F(\varepsilon, \partial_\mu \varepsilon)$ encodes the local “elastic” cost of deviations from perfect coherence $\varepsilon = 1$, R is the scalar curvature of the spacetime metric $g_{\mu\nu}$, and $\kappa = 8\pi G/c^4$.

A.2 Variations and Field Equations

(a) **Variation with respect to ε .** Stationarity of the action yields

$$\frac{\delta F}{\delta \varepsilon} - \nabla_\mu \left(\frac{\partial F}{\partial (\nabla_\mu \varepsilon)} \right) = 0, \quad (74)$$

which represents the internal relaxation of informational stress inside the holographic field.

(b) **Variation with respect to $g_{\mu\nu}$.** Metric variation gives

$$G_{\mu\nu} + \Lambda g_{\mu\nu} = \kappa T_{\mu\nu}^{(I)}, \quad (75)$$

where the **informational stress–energy tensor** reads

$$T_{\mu\nu}^{(I)} = -\frac{2}{\sqrt{-g}} \frac{\delta(\sqrt{-g} F)}{\delta g^{\mu\nu}}. \quad (76)$$

A.3 Interpretation

Equations (74)–(75) express the equilibrium of two subsystems: the informational field $\varepsilon(x)$ and the spacetime geometry $g_{\mu\nu}$. Gradients of ε act as informational sources, and curvature redistributes them so that the total informational flux is divergence-free:

$$\nabla_\mu T_{(I)}^{\mu\nu} = 0.$$

Geometric meaning. Equation (75) shows that gravitational curvature is the macroscopic signature of the Universe restoring global informational balance. Gravity therefore appears not as a fundamental force, but as the geometric response of the manifold to gradients of informational density ensuring $\varepsilon + \delta = 1$ at all scales.

Figure 5: **Informational curvature as dynamic equilibrium.** Regions of information density inhomogeneity (blue shading) induce curvature $R(g)$ restoring global balance. The result reproduces Einstein’s equation as the metric form of the equilibrium condition $\nabla_\mu T_{(I)}^{\mu\nu} = 0$.

A.4 Summary

Starting from a single postulate of *dynamic informational equilibrium*, the standard Einstein field equations follow as the variational condition for the metric component of the informational action (73). In this framework, spacetime curvature is the emergent pattern that maintains the conservation of total information in
